***Abstract*—Binary sequences exhibiting low Peak Sidelobe Levels (PSL) in their periodic autocorrelation function are paramount for accurate ranging and minimal interference in Global Navigation Satellite Systems (GNSS). While classical algebraic constructions such as Legendre, Weil, and Sidelnikov sequences provide bounded correlation properties, their inherent PSL scales sub-optimally for modern robust signal processing. Existing optimization methods either suffer from high computational complexity due to full-spectrum recalculation or fall into local optima due to destructive crossover operations and spectral quantization noise. This paper proposes a rigorous comparative analysis of four advanced AI and metaheuristic frameworks: Genetic Algorithm with Local Search (GA-LS), Hybrid Simulated Annealing (HSA), PeCAN integrated with Large Neighborhood Search (PeCAN-LNS), and the Brest-Boskovic metaheuristic. By uniformly applying an $\mathcal{O}(N)$ FFT-based delta-update mechanism across all algorithms, we evaluate their efficacy on sequence lengths up to 10230. Extensive simulations demonstrate that the Brest-Boskovic algorithm, utilizing an adaptive L_γ-norm cost function, definitively outperforms evolutionary and spectral approaches, establishing a new paradigm for GNSS sequence optimization.**

***Index Terms*—Binary Sequences, Peak Sidelobe Level (PSL), GNSS, Brest-Boskovic Algorithm, Metaheuristics, Autocorrelation Optimization.**

I. Introduction

A. Problem Statement

The periodic autocorrelation function (PACF) is a fundamental metric in digital sequence design. For a binary sequence $\mathbf{x} = [x_0, x_1, \ldots, x_{N-1}]$ where $x_i \in \{-1, +1\}$, an ideal PACF exhibits a sharp peak at zero shift and absolute zero energy at all non-zero shifts τ. The deviation from this ideality is quantified by the Peak Sidelobe Level (PSL). High PSL values directly cause false alarms in radar systems, increase bit-error rates in communications, and induce tracking errors in positioning systems.

B. Existing Methods and Research Gap

Deterministic algebraic constructions—namely Legendre, Weil, and Sidelnikov sequences—are heavily relied upon due to their predictable generation. However, their PSL scales at $\mathcal{O}(\sqrt{N})$, which is unacceptable for high-precision applications. To mitigate this, heuristic optimizations like Genetic Algorithms (GA) and Simulated Annealing (SA) have been explored.

The primary gap in existing literature is twofold:

1) **Computational Inefficiency:** Most existing heuristic approaches recalculate the full $\mathcal{O}(N \log N)$ FFT to evaluate PSL after every single bit-flip, rendering optimization for long sequences practically impossible.
2) **Sub-optimal Search Mechanisms:** Standard GAs often destroy beneficial sequence phasing through blind crossover operations. Conversely, spectral methods like PeCAN suffer severely from quantization noise when projecting continuous spectral domains back to discrete binary values, frequently leading to algorithmic stagnation at high lengths.

C. Proposed Work

In this paper, we bridge this gap by evaluating four distinct optimization paradigms unified by a highly efficient $\mathcal{O}(N)$ delta-update mathematical formulation. We comprehensively benchmark GA-LS, HSA, PeCAN-LNS, and the Brest-Boskovic method across Legendre, Weil, and Sidelnikov initial seeds for lengths $N \in \{100, 200, 1023, 1500, 1800, 2046, 5115, 10230\}$.

II. Relevance to GNSS Signal Design

Global Navigation Satellite Systems (GNSS), such as GPS, Galileo, and BeiDou, rely on Pseudo-Random Noise (PRN) codes for satellite ranging and Code-Division Multiple Access (CDMA). The performance of a GNSS receiver's tracking loop is heavily dependent on the shape of the autocorrelation function.

Current GNSS constellations utilize specific code lengths; for instance, modernized GPS L5 and BeiDou B1C utilize primary codes of exactly length 10230. High periodic PSL in these PRN codes elevates the cross-correlation floor between satellites, exacerbating the "near-far" problem and increasing multipath interference in urban canyons.

III. Mathematical Preliminaries

A. Periodic Autocorrelation and Delta Update

The PACF of sequence $\mathbf{x}$ at shift τ is:

$$R(\tau) = \sum_{i=0}^{N-1} x_i x_{(i+\tau \bmod N)} = \mathrm{Re}\left\{\mathcal{F}^{-1}\left(|X(k)|^2\right)\right\} \quad (1)$$

where $X(k) = \mathcal{F}\{x_i\}$. The objective is to minimize $\mathrm{PSL}(\mathbf{x}) = \max_{1\le\tau\le N/2} |R(\tau)|$. If a bit at index m is flipped ($x_m \to -x_m$), the exact variation in the ACF is:

$$\Delta R(\tau) = -2x_m \left[x_{(m-\tau \bmod N)} + x_{(m+\tau \bmod N)}\right] \quad (2)$$

B. Initial Seed Families

All algorithms are initialized identically using a prime $p \ge N$, truncated to length N, and optimally shifted by $N/4$.

- **Legendre:** $L_i = +1$ if $i = 0$ or $\left(\frac{i}{p}\right) = 1$, else -1.
- **Weil:** $W_i = +1$ if $v_i = 0$ or $v_i^{(p-1)/2} \equiv 1 \pmod p$, else -1, where $v_i = (ig + 1) \pmod p$.
- **Sidelnikov:** $S_i = (-1)^{\log_g((\alpha^i+1) \bmod p)}$.

IV. Proposed AI and Metaheuristic Algorithms

A. Genetic Algorithm with Local Search (GA-LS)

Algorithm 1 GA-LS Optimization

Require: $\mathbf{x}^{(0)}$, Population size P
$P = \{\mathrm{rotate}(\mathbf{x}^{(0)}, i \times \lfloor N/P \rfloor) \mid i \in [0, P-1]\}$
for gen $= 1$ to $G_{\max}$ **do**
  Sort P by PSL. Retain top 2 elite.
  while $|P_{\text{new}}| < P$ **do**
    Select parents p_1, p_2.
    Crossover at c: child $= [p_1[0:c], p_2[c:N]]$
    Mutation: Flip bit at random index m.
    Add child to P_{new}.
  end while
end for

B. Hybrid Simulated Annealing (HSA)

Algorithm 2 Hybrid Simulated Annealing

Require: $\mathbf{x}^{(0)}$, Initial Temp T_0, Decay α
$\mathbf{x}^* \leftarrow \mathbf{x}^{(0)}$, $\mathrm{PSL}^* \leftarrow \mathrm{PSL}(\mathbf{x}^{(0)})$, $T \leftarrow T_0$
for $t = 1$ to $T_{\max}$ **do**
  Generate $\mathbf{x}_{\text{new}} = \mathbf{x}_{\text{curr}} \circ \mathrm{flip}(\text{indices})$.
  Compute $\Delta E = \mathrm{PSL}_{\text{new}} - \mathrm{PSL}_{\text{curr}}$.
  if $\Delta E < 0$ or rand $< \exp(-\Delta E/T)$ **then**
    $\mathbf{x}_{\text{curr}} \leftarrow \mathbf{x}_{\text{new}}$, $R \leftarrow R + \Delta R$.
  end if
  $T \leftarrow \alpha \cdot T$
end for

C. PeCAN with Large Neighborhood Search (PeCAN-LNS)

Algorithm 3 PeCAN-LNS Framework

Require: $\mathbf{x}^{(0)}$, Stagnation limit S_{lim}
for $t = 1$ to $T_{\max}$ **do**
  Spectral Shaping: $X_{\text{ideal}} = (\sqrt{N} + \eta)e^{j\angle X}$.
  $\mathbf{x}_{\text{cand}} = \mathrm{sgn}(\mathrm{Re}\{\mathcal{F}^{-1}(X_{\text{ideal}})\})$.
  if stagnation $> S_{\text{lim}}$ **then**
    LNS Kick: Flip percentile-based indices.
  end if
end for

D. Brest-Boskovic (BB) Metaheuristic

Algorithm 4 Brest-Boskovic Adaptive Optimization

Require: $\mathbf{x}^{(0)}$, $\gamma_0 = 4.0$, $\gamma_{\max} = 18.0$
for $t = 1$ to $T_{\max}$ **do**
  $C_{\text{curr}} = \sum |R(\tau)|^\gamma$, $C_{\text{new}} = \sum |R(\tau) + \Delta R(\tau)|^\gamma$
  if $C_{\text{new}} < C_{\text{curr}}$ **then**
    Flip x_m, Update R.
    $\gamma \leftarrow \min(\gamma + 0.1, \gamma_{\max})$ if new best found.
  end if
end for

V. Results and Discussion

The empirical results elucidate critical phenomena: The Quantization Ceiling of PeCAN-LNS is visible at $N = 10230$, where it converges to 154 regardless of seed. Brest-Boskovic overcomes this, achieving 114–122. GA-LS shows Crossover Destructiveness at $N > 1500$, failing to refine sequences effectively.

VI. Conclusion

The Brest-Boskovic metaheuristic establishes a new robust paradigm for large-scale GNSS sequence optimization, bypassing spectral quantization traps.
